RAINDROP SIZE DISTRIBUTIONS AND Z-R RELATIONSHIPS MEASURED ON THE
NOAA DC-6 AND THE NOAA SHIP RESEARCHER WITHIN THE GATE B-SCALE ARRAY

John B. Cunning and Robert I. Sax

A better understanding of how the precipitation budget operates in tropical convective systems is a prime objective of the GATE research effort. Measurement of rainfall rate with shipboard radar is the principle method by which precipitation output from tropical clouds that develop within the GATE B-scale array will be determined. Knowledge of the relationship between radar reflectivity (Z) and rainfall rate (R) is essential for an accurate interpretation of precipitation data derived through the use of radar technology. The Z - R relationship is determined through application of a least-squares linear regression to data points derived by appropriate integration of the third and sixth moments of a series of raindrop size spectra.

Drop spectra measurements were obtained during GATE by means of a foil impactor operated at cloud-base level on board the NOAA DC-6 aircraft and a surface-based raindrop distrometer operated on the flying bridge of the NOAA ship "Researcher." A total of 107 and 137 Z - R data points are available from the foil impactor and distrometer data respectively. These represent showers occurring on 12 days in the case of the foil data, and on 8 days in the case of the distrometer data. The best-fit Z - R relationship for the cloud-base aircraft foil data showed little variability from day to day or on the basis of stratification by rain rate. For all foil data combined, the best-fit Z - R relationship was found to have the form:

$$Z = 170R^{1.52}$$

which gives, for example, rain rates of 66, 15, and 3 mm hr^{-1} for Z values of 50, 40, and 30 db respectively.

Drop spectra measurements derived from the distrometer data required the application of a correction scheme to the small end of the distribution because of the apparent insensitivity of that device for detecting small drops in the shipboard noise environment. These corrections led to appreciable changes in the rain rates computed through a mass integration of the drop spectra and, for that reason, the Z - R relationship derived from the distrometer data, provided in the text, must be regarded with some suspicion.

Discussion of the use of a cumulative distribution function to transform drop spectra derived from the foil data is provided in an appendix. The advantage of this technique lies in the alleviation of sampling volume problems occurring at the large end of the drop size distribution.

1. INTRODUCTION

The release of latent heat of condensation is one of the primary energy sources available to drive the tropical weather machine. The way that this energy source is utilized locally within a tropical area cannot be determined without detailed knowledge of the water budget within cloud systems. As stated by Weickmann (1973), three essential parameters must be measured:

- a) the rate of condensation and deposition (production of liquid water or ice) occurring within a cloud system, which determines the amount of latent heat taken from the environment,
- b) the precipitation of water, which determines the quantity of latent heat released by the cloud system,
- c) the amount of water remaining within the cloud system.

From these considerations it followed that a project such as the GARP Atlantic Tropical Experiment (GATE), which had as a goal the understanding of tropical convective processes, required a cloud physics subprogram to investigate the degree to which nature utilizes the available condensational energy within mesoscale cloud systems. Some important parameters to be measured included influx of water vapor through cloud base, in-cloud water content at various levels, entrainment characteristics, and precipitation rates, distributions, and amounts.

The GATE Project gave researchers the opportunity to investigate tropical convective processes on a subsynoptic scale over an oceanic region well removed (500 to 1000 km) from any major land mass (fig. 1). Quantitative radar

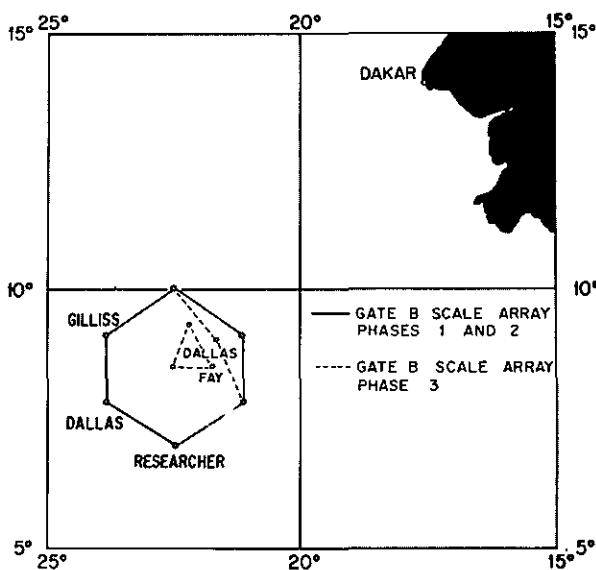

measurements were used within the GATE B-scale array to provide information about hydrometeor water content within convective systems and on total precipitation amounts. The shipboard radars used in GATE were principally C-band with wavelengths of 5.6 cm. Since, for a 5.6-cm wavelength, the Rayleigh scattering approximation is valid for all but the largest of raindrops, the radar reflectivity, Z , can be computed from the expression

$$Z = \int N(D)D^6 dD \quad (1)$$

where $N(D)$ is the drop concentration per unit volume, D is the drop diameter, and Z is expressed in the units $\text{mm}^6 \text{ m}^{-3}$. The rainfall rate R (mm hr^{-1}) can be calculated from the equation

$$R = \frac{\pi}{6} \int N(D)D^3 \rho V_t dD \quad (2)$$

Figure 1. Location of GATE B-scale array and participating ships.

where ρ is the density of water and V_t is the terminal velocity of raindrops of diameter D . An understanding of the relationship between Z and R is of fundamental importance for the quantitative determination of rainfall rates from radar.

This paper discusses drop size distributions obtained by both an airborne foil impactor and a shipborne distrometer and provides an analysis of the relationship between radar reflectivity and rainfall rate within the GATE B-scale array.

2. VARIABILITY OF Z-R RELATIONSHIPS

It has been established by many investigators that a relationship of the form $Z = aR^b$, with Z and R both functions of the drop size distribution, can be used for a variety of rainfall types in a number of geographical locations. Table 1, a summary of previously published Z-R relationships from different regions of the world, shows that the coefficient a has been found to vary from 17 to 730 and that the exponent b has been found to vary from 1.16 to 2.87. More strikingly, for an arbitrary value of Z of $10^5 \text{ mm}^6 \text{ m}^{-3}$ (50 dB), the corresponding rainfall rate is found to range from 10 mm hr^{-1} to 270 mm hr^{-1} . Even if the several extreme values of a and/or b are ignored, the range of rainfall rate R when Z is 50 dB is still about an order of magnitude. It is not surprising that stratification by geographical location (e.g., maritime, continental, or tropical) and shower type (convective or stratiform) is a necessary first step in determining applicability of a particular Z-R relationship.

Since many of the formulations in table 1 were derived from data based upon minimal drop sampling volumes, Z-R variability from shower to shower or day to day, or both, may have not been reflected. Measurements to determine the Z-R variability within a given area or rainfall regime should be made repeatedly to enable accurate computations of rainfall rates. It is also likely that measurements obtained on the periphery of the rain shower core (either in terms of space or time) may not be representative and may serve to add noise to the data. Table 2 contains data from Stout and Mueller (1968), derived from surface drop camera measurements, that show variability of the Z-R relationship at Miami as a function of rainfall type, synoptic condition, and instability criteria.¹ In the case of the last parameter, the rain rate for an arbitrary Z value of 50 dB ranges from 48 mm hr^{-1} for an instability category of 7 to 110 mm hr^{-1} for an instability category of 10 (lowest instability stratification). The maximum variability when rainfall is stratified as to type or synoptic condition is about a factor of 2, which can still provide appreciable differences at a Z value of 50 dB. This serves to emphasize the highly variable nature of drop distribution data and points to the need for a determination of the Z-R relationship for a particular set of known meteorological and geographical parameters.

¹Defined by Stout and Mueller (1968) as the amount of energy required to lift a parcel of air through the troposphere; results of calculations were grouped and stratified into 10 categories in descending order of instability.

Table 1. Various Published Z-R Relationships (from Battan, 1973, with changes)

Equation	Reference	Location	Remarks	R(mm hr^{-1}) for Z=50 db

3. MEASUREMENT PROGRAM

3.1 Motivation for Experimental Design

The calculation of a Z-R relationship that would be appropriate for the oceanic region encompassed by the GATE B-scale array requires that the size distribution of raindrops be measured on shipboard and/or from aircraft operating within that area. Since spectra measurements contain high natural spatial and temporal variability (primarily because of sampling volume limitations of instrumentation currently in use), it is important to compensate for possible error by calculating ensemble averages from a sample size that is large enough for statistical significance. Furthermore, it is absolutely necessary that the shower core, not just the periphery, be sampled for the computation of a meaningful Z-R relationship.

Garstang (1969) showed that during the 1968 Barbados Experiment the NOAA ship *Discoverer*, stationed in the eastern tropical North Atlantic near Barbados from August 4 to 27 was in a significant shower (greater than 2.5 mm hr^{-1} of rainfall) on only 10% of the experimental days. Holle (1968) found, however, that precipitation from at least one cloud within a 30-km radius of the R/V *Crawford* stationed in the tropical Atlantic near Barbados in the summer of 1963 occurred during 60% of all hours having supporting photographic data. This indicates that, although the occurrence of a shower directly overhead at a given location in the tropical ocean is a rather rare event, the occurrence of precipitation within a surrounding extended area is a frequent event. Thus, measurement from a highly mobile instrumented platform, such as an aircraft, should be used in conjunction with those from one or more fixed-ship platforms to obtain a large ensemble average of drop size distributions over an oceanic area.

3.2 The Aircraft Program

The U. S. aircraft program to obtain drop size distributions within the GATE area was quite extensive. The primary instruments for this purpose were an MRI foil impactor and a Knollenberg 1-D particle spectrometer (cloud droplet and raindrop probes). Both the NOAA DC-6 and C-130 aircraft carried foil impactors during the three phases of GATE (first phase - June 28 to July 16, 1974; second phase - July 28 to August 17, 1974; third phase - August 30 to September 19, 1974). During the second phase a Knollenberg 1-D particle spectrometer (cloud and rain probes) was carried on the DC-6 aircraft, but the raindrop probe was transferred to the C-130 aircraft for the third phase. A Knollenberg 1-D drop spectrometer (cloud and rain probes) was carried on the NCAR Electra for the three phases and on the NCAR Sabreliner (cloud probe only) during the second and third phases.

During the GATE experiment, the DC-6 aircraft operated mainly at an altitude near cloud base, the NCAR Electra operated at altitudes between cloud base and 10,000 ft, the C-130 aircraft flew typically at the freezing level (15,000 ft) or colder, and the Sabreliner flew at very high altitudes ($>30,000$ ft). The aircraft sections of this paper are concerned only with data obtained from the foil impactor operated on the DC-6 aircraft near the cloud-base level.

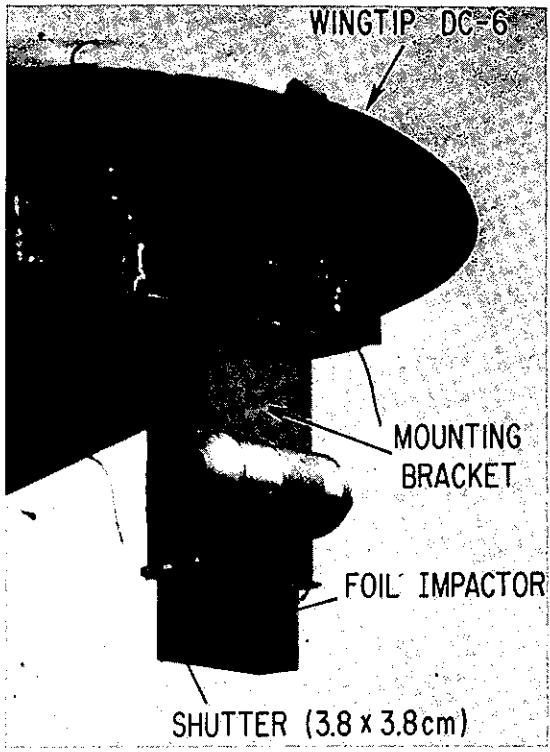

Figure 2. Foil impactor of MRI design mounted on the wingtip of the NOAA DC-6 aircraft. The foot-ball-shaped cylinder directly above the impactor is an optical ice particle counter.

convective element (approximately 3 km in diameter). When fully loaded, the impactor can carry about 9000 cm of foil, enough to obtain measurements from about 10 to 20 rain shafts of the sizes typically encountered within the area covered by the GATE B-scale array.

3.3 Surface Program

The U. S. program to measure drop size distributions at the surface was carried out on GATE ships at fixed locations within the B-scale array (fig. 1). Distrometers of the type developed by Joss and Waldvogel (1967) were used exclusively by the U. S. participants. During the three GATE phases, the NHEML distrometer was on the NOAA ship *Researcher*, and a second distrometer operated by the Department of Meteorology, Massachusetts Institute of Technology, was on the *R/V Gilliss*. A third distrometer, operated by the Department of Physics, University of Toronto, was on the Coast Guard ship *Dallas* during the first phase and on the *R/V Fay* during the third phase of GATE. The surface

²Foil used during GATE on the NOAA DC-6 had a thickness of .001 inch and was purchased from Clecon Metals, Cleveland, Ohio, with their alloy specification 1145-0, pack roll finish, on 1-5/16 inch I.D. flush fiber core.

program sections of this report are confined to a discussion of results obtained by the distrometer operated on board the NOAA ship *Researcher*.

The distrometer was located on the flying bridge of the *Researcher*, a site chosen for its good exposure to rain, reduced background noise, and proximity to the center of gravity for minimal ship vertical motion. The distrometer was activated manually whenever showers passed over the ship. The transducer and processor system (fig. 3) provides an electronic signal (0 to 10 v pulse of 500 ms duration) proportional to the momentum transfer of raindrops impacting upon the distrometer head. The signal is pulse-height analyzed, digitized, formatted into standard two-track NRZI serial data, and recorded on a Uher Model 4200 tape recorder. The conical sampling head has a cross-sectional exposure area of 50 cm^2 . The sampling volume per unit time is proportional to the terminal velocity of the raindrops. For a 120-second interval, the sampling volume of the distrometer for raindrops 1 mm in diameter is about 2 m^3 , while, for raindrops 5 mm in diameter, the sampling volume is nearly 5.5 m^3 .

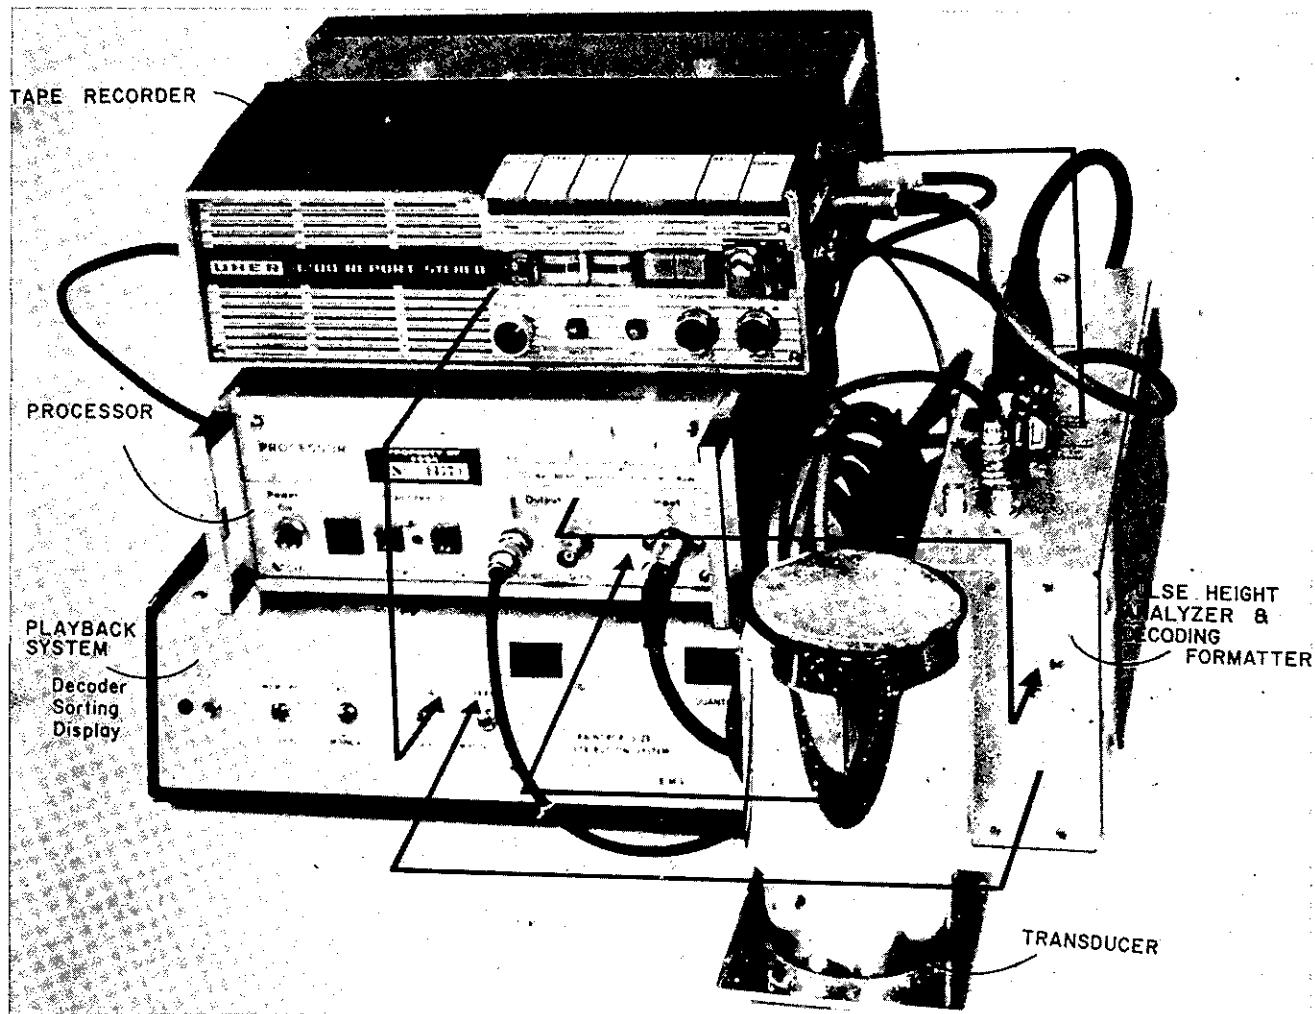

Figure 3. NHEML raindrop distrometer package. Shown are the Joss transducer and processor, pulse height analyzer, tape recorder, and NOAA-designed playback system.

4. DATA ANALYSIS TECHNIQUES

4.1 Aircraft Data

Upon completion of each flight day, the foil from the impactor device was dried to prevent corrosion. The data were checked to determine whether the impactor was operating properly and were cataloged for delivery to the U. S. At the conclusion of GATE, all foil data were inch-marked for time and length continuity and subsequently analyzed on a frame-by-frame basis with a Bausch and Lomb Quantitative Metallurgical System (QMS). The QMS is an electro-optical system that employs a vidicon camera and associated logic circuitry to allow for fast, automated measurements of a spectrum of particle sizes.

The analyzed foil data were sorted into 10 .50-mm size categories, the first being $0 < D \leq .50$ mm and the tenth being $4.5 \text{ mm} < D \leq 5.0$ mm. A correction, similar to that used by Schecter and Russ (1970), was applied to the drop imprint diameters to account for spreading of the liquid upon impact with the foil.³ The terminal velocity expression used in the calculation of the rainfall rate (2) for the aircraft data was derived by Foote and Dutoit (1969) to fit the empirical data of Gunn and Kinzer (1949) and has the form

$$V_0 = \sum_{j=0}^N a_j d^j \quad (3)$$

where the subscript zero refers to conditions at 20° C and 1013 mb, d is drop diameter, and a_j is determined from a least-squares curve fitting technique. A ninth-degree polynomial ($N = 9$) was used in the calculation of a_j . An altitude correction for $V(d)$ as discussed by Foote and Dutoit (1969) was also applied, but in the case of the DC-6 foil data collected at or below about 3,000 ft, such a correction was negligible.

A single drop size distribution is derived for each aircraft penetration through a precipitation core region. For statistical validity (see Appendix C) each drop-size distribution typically has an integrated sample size of at least several hundred drops. Finally, from the number concentration of drops in each of the 10 size categories, a value of radar reflectivity (1), rainfall rate (2), and other related variables, such as liquid water content and slope of the best fit curve to the drop size spectra, are calculated for each aircraft traverse through a precipitation core region. A discussion of statistical criteria for the representativeness of drop size distributions sampled with a device such as a foil impactor and techniques for using a transformation function to calculate the drop size distribution is provided in Appendix C.

³The expression used in this work has the form:

$$D_{ACT} = 0.865 D_{IMG}$$

It was derived and has been applied by Francis J. Merceret (personal communication) as a simplistic linear best fit to the Schecter and Russ size calibration data.

4.2 Surface Data

Upon completion of the operational phases of GATE, each tape from the distrometer recording system was played back through a processing and display unit. Each tape could contain up to about 48 minutes of rainfall data. It was usual procedure to record each new shower on a fresh tape, so many tapes were only partially filled with data. To achieve the maximum number of individual drop spectra (and hence Z-R data points) per shower while, at the same time, maintaining a sample volume judged adequate for the accumulation of a representative concentration of drops in each bin size, we decided to calculate each drop size distribution on the basis of uniform 120-second time intervals. This allowed a maximum of 24 distributions (Z-R data points) per data tape. In almost all cases selected for detailed study, the integrated number of drops in each 120-second interval was at least 100. Two-minute segments of distrometer data containing much fewer than 100 drops (integrated through all bin sizes) were not considered for further analysis.

The data processing package allowed each pulse-height analyzed drop to be placed into one of 64 discrete size intervals with the maximum drop diameter in mm for each drop size category given by the expression

$$D = 0.3071M^{0.65789} \quad (4)$$

where M is the category number (1-64). The range of sizes associated with each bin is variable, but generally is between .06 and .09 mm. The terminal velocity in cm sec^{-1} corresponding to the drop size at the midpoint of each category was calculated according to a formulation expressed by Best (1950),

$$V_T = K \left\{ 1 - \exp [-(d/a)^n] \right\} \quad (5)$$

where d is the drop diameter in millimeters and K, a, and n are constants with values of 943, 1.77, and 1.147, respectively. Table 3 provides a complete summary of the minimum, midpoint, and maximum drop diameters, vertical velocity, and sampling volume (for a sampling period of 120 seconds) associated with each bin size. Several successive bins can be combined through the range of bin sizes to obtain a uniform bin spacing of .25 mm. This is done in an effort to smooth irregularities in the drop spectrum resulting from processing of bin sizes too small to allow the accumulation of a representative sample of drops in each bin. The .25-mm uniform bin size selected for the distrometer analysis is about half that (.43 mm) used in the processing of the foil data. Table 4 summarizes the combined bin size information, with the midpoint diameter, terminal velocity, and sampling volume corresponding to a 120-second sampling period given for each bin size.

5. RESULTS - AIRBORNE PROGRAM

Measurements of drop size spectra were obtained during each phase of GATE with the majority of data collected during the second phase. Table 5 gives the dates, duration, altitudes, and aircraft mission type from which data were collected. As can be seen from table 5, a large amount of data, totaling in excess of 76,000 cm of foil, was collected on 21 days during GATE. The days selected for analysis were those on which more than 2000 cm of foil were

* Dates analyzed with more than 2000 cm of foil.

collected. For the 12 days that met the 2000-cm criterion, more than 70,000 cm of foil were analyzed from 107 rainshaft penetrations. The flight altitudes of the DC-6 generally varied between 300 and 1500 ft, although several penetrations were carried out at an altitude higher than 3000 ft. A complete listing of the drop size distributions from each rainshaft penetration is given in Appendix A.

Figures 4a through 4f show composited drop distributions for various rainfall rates. The dotted line indicates the mean distribution and the shaded area indicates two standard deviations away from the mean. None of the composited distributions showed any marked differences as a function of altitude within the range of observations and, for ease of classification, will be categorized together as cloud-base distributions. Figure 5 shows drop size distributions for five rainfall rates on August 10, 1974. The distributions indicate that, for light to moderate rainfall rates, the spectrum decays exponentially for drop diameters larger than about 1 mm. For the heavier rain rates, the exponential decay commences near a diameter of 1.5 mm. The best-fit curve to the drop size distributions given in figure 5 assumes the form:

$$N(D) = N_0 e^{-\lambda D} \quad (6)$$

where N_0 is the intercept and λ is the slope of the best-fit line.

Through the use of (1) and (2), Z-R data points can be computed from each drop size distribution to derive a Z-R relationship. Table 6 summarizes the Z-R relationships on a day-to-day basis for the 12 days analyzed for GATE. The best-fit curves for eight days during which drop size distributions were obtained from seven or more rainshaft penetrations are shown in figure 6. It is not possible to discern any significant day-to-day variation as a function of either flight altitude or mission type. Table 7 gives the rainfall rates (mm hr^{-1}) as a function of $Z(\text{dB})$ for the eight days shown in figure 6. It can be seen that, for radar reflectivity values between 35 and 50 dB, the daily variability of the computed rainfall is quite small. A divergence of the calculated daily rainfall rates is noted for $Z(\text{dB})$ values $< 35 \text{ dB}$ and $> 50 \text{ dB}$. Only in the latter case, that of extremely heavy rain rates, is the daily variability likely to be of any practical consequence to the determination of radar-derived rainfall.

Since, at reasonable rain rates, there is no indication of high variability on a day-to-day basis or from mission type to mission type, the total data set for the 107 Z-R points can be combined to derive an averaged Z-R relationship. Figure 7 shows all of the individual Z-R points and the best-fit line to the points derived from a regression of Z , the dependent variable, on R , the independent variable. The Z-R relationship

$$Z = 170R^{1.52} \quad (7)$$

has a correlation coefficient of .986, and this relationship is put forward as the cloud base Z-R relationship for the GATE area.

$$Z (\text{db}) = 10 \log Z_0 (\text{mm}^6 \text{m}^{-3}); \quad Z = aR^b$$

$$R (\text{mm hr}^{-1}) = \left(\frac{Z_0}{a} \right)^k \quad \text{where} \quad k = \frac{1}{b}$$

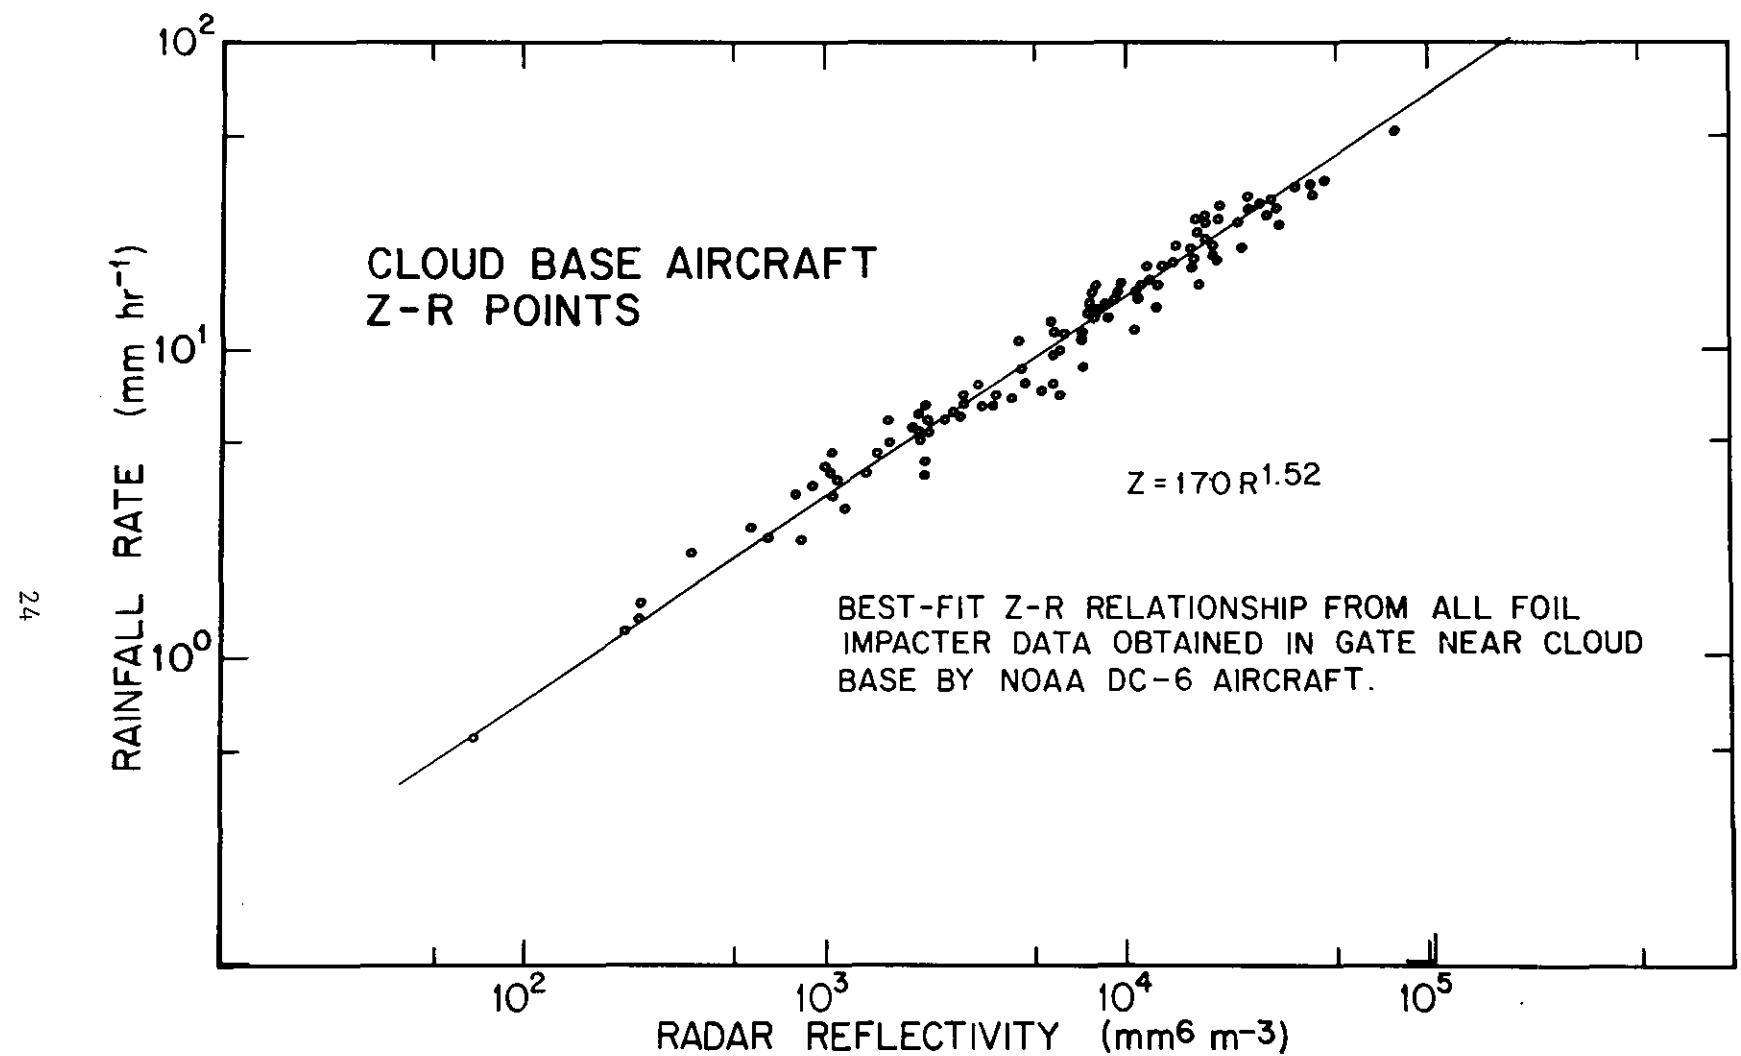

Figure 7. Best-fit Z-R relationship drawn to all data points obtained through an analysis of DC-6 foil data collected near cloud base within the GATE B-scale array.

Table 8 provides an additional stratification of the total set of Z-R points as a function of rainfall rate. Here, all the Z-R points greater than the R values indicated in the first column are used to calculate a Z-R relationship. It can be seen that the rainfall rates computed for 50, 45, 40, and 35 dB are, for all practical purposes, completely unaffected by the stratification by rainfall rate. This is displayed graphically in figure 8 where the best-fit Z-R relationship is plotted to data points (not shown) stratified as a function of rainfall rate. The best-fit lines to three values of rainfall rate ($R > 0$, $R > 7.5 \text{ mm hr}^{-1}$, and $R > 12.5 \text{ mm hr}^{-1}$) are shown. Lines drawn to intermediate rainfall values would fall superimposed on the three shown. This indicates that the best-fit Z-R relationship is not unduly weighted by a predominance of data points at any given rainfall intensity.

6. RESULTS - SHIPBORNE PROGRAM

Measurements of raindrop size distributions were taken on board the NOAA ship *Researcher* during the three phases of GATE. Table 9 presents the dates, number of showers, number of showers analyzed, and the GATE convective code for that day.⁴ The table indicates that only nine showers, accounting for 137 individual distributions, were analyzed from a possible total of 42. This was partly the result of a signal-to-noise problem that is inherent in the distrometer and partly a consequence of many showers being too light (sampling on the periphery instead of the core) to insure an adequate number of drops recorded in an acceptable number of bins to derive a representative distribution.

Figure 9 shows five drop size distributions from the distrometer for various rainfall rates recorded on June 30, 1974. Unlike most drop spectra which are characterized by an exponential decay, the distrometer distributions do not exhibit such a shape for drop diameters $< 2 \text{ mm}$. This feature in the drop spectrum is most likely the result of a detection problem of the distrometer that occurs when it is placed in a high background noise environment. The distrometer transducer is basically similar to a microphone that cannot only detect raindrops, but which is also sensitive to background noise. The processor unit of the distrometer has a noise-suppression circuit which acts to level shift the mean detectable signal to filter out the background noise. However, this circuit also eliminates the detection of all raindrops that have a signal intensity less than the level-shifted mean detectable signal.

In the shipboard environment, the background sound level was very high with the presence of continuous generator and motor noise. The result of this high background noise for the distrometer measurements is that all drop sizes $< 1 \text{ mm}$ were completely eliminated, and the number of drops recorded in the 1- to 2-mm range was greatly reduced. An attempt has been made to account for this problem in the analysis by extrapolating a best-fit curve to the distribution of drop sizes not affected by the noise problem back to small drop diameters in a consistent manner. Figure 10 illustrates how the drop size distributions for the five rainfall cases on June 30 (shown in figure 9) can

⁴A detailed description of this convective code adopted by the GATE ships is found in GATE Information Bulletin #8, September 1, 1975.

Table 8. Cloud-Base Best-fit Z-R Relationships as a Function of Rainfall Rate

Stratification	No. data points	Z-R relationship	Correlation coefficient	R at 50 db mm hr ⁻¹	R at 45 db mm hr ⁻¹	R at 40 db mm hr ⁻¹	R at 35 db mm hr ⁻¹
All data	107	$Z = 170 R^{1.52}$	0.986	66	31	15	7

be modified by extrapolating backwards from the large end of the spectrum. The most logical way to test the validity of this technique from available data was to compare the derived precipitation amounts from the integrated modified distrometer distributions to those from the siphon gages (located on the mast and boom) or from the wedge gages (located elsewhere on the ship).

Table 10 shows the 6-minute averaged precipitation amounts for the siphon gage, the indicated distrometer, and the corrected (modified) distrometer data for a shower which passed over the Researcher on July 8, 1974. The corrected distrometer amounts are slightly less than those for the siphon gage, but provide a much better comparison with the gage than do the uncorrected distrometer amounts. The siphon gage data were available for September 4 and 16, 1974, and a similar correction procedure was carried out for those days. Siphon gage data were not available coincident with usable distrometer data on any other day. The available wedge gage data were unsuitable as a basis for intercomparison with the distrometer because the gages were read too infrequently (once every 6 hours). It was decided, therefore, that for these cases, the best way to correct the distrometer was to extrapolate the drop size distributions back to small drop diameters in the same manner as that which had been applied to the three days with siphon gage data.

Figure 11 shows composited drop distributions (from the uncorrected data) for eight rainfall rates. The solid line indicates the mean distribution and the shaded area is a measure of two standard deviations away from the mean. These composites appear to exhibit the same general trends as a function of rain rate as those from the aircraft, although the drop concentrations at small diameters ($D < 2$ mm) generally are reduced compared with those from the aircraft (sampling problem just discussed), and these distributions are somewhat narrower (fewer large drops) than are those from the aircraft. A complete listing of the drop size distributions for each 120-second interval of each shower is given in Appendix B, both for the raw (uncorrected) and modified distrometer data.

Again, through the use of (1) and (2), Z-R points can be derived from each drop size distribution. Table 11 presents the Z-R relationship for the actual and modified distribution for each of the nine showers sampled. Figures 12 and 13 show the shower-to-shower variability for the Z-R relationship derived from the modified and unmodified drop distribution data, respectively. It can be seen that the daily variability of the Z-R relationship derived from the distrometer data is considerably greater than that derived from the foil impactor data shown in section 5. This is particularly true in the case of the modified data set. Table 12 gives the rainfall rates (mm hr^{-1}) as a function of $Z(\text{dB})$ for the eight modified case days shown in figure 10. The rainfall rate variability from case to case within the $Z(\text{dB})$ range of 35 to 50 is considerably greater than that derived from the foil data shown in table 7.

Since all the distrometer data is taken from approximately the same fixed location, and since there are not enough shower cases to determine the Z-R variability as a function of different types of synoptic conditions, the total data set was combined to derive an averaged Z-R relationship. Figure 14 shows all of the modified Z-R points along with the best fit line to the points.

obtained by regressing the dependent variable Z on the independent variable R has a correlation coefficient of .97, and it is this relationship around which discussions of the distrometer-derived surface Z-R relationship for the GATE area⁵ in section 7 are based.

Table 13 provides an additional stratification of the distrometer-derived best-fit Z-R relationship as a function of rainfall rate. It can be seen that the elimination of the 33 data points associated with light rainfall rates ($< 5.0 \text{ mm hr}^{-1}$) results in a Z-R relationship with a greater slope and tends to decrease R at a high value of Z (50 dB). The change in R for moderate values of Z (35 dB to 45 dB) is not strongly noticeable, however. Figure 15 provides the best-fit Z-R relationship curves drawn to data points (not shown) stratified as a function of three rainfall rates ($R > 0$, $R > 7.5 \text{ mm hr}^{-1}$, and $R > 12.5 \text{ mm hr}^{-1}$). The best-fit lines for the other rainfall rates given in table 13 would fall between those shown in figure 15.

7. DISCUSSION OF RESULTS

The drop spectra measurements obtained during GATE with the foil impactor on the NOAA DC-6 aircraft provide a consistent set of derived Z-R relationships that have only minor, day-to-day variability (fig. 6). The practical consequence of this is shown in table 7, where it can be seen that, within the range of the highest⁶reflectivity values (30 to 50 dB) that are most likely to occur, similar rainfall rates are computed from each of the daily Z-R relationships. Stratification of the foil-derived set of Z-R data points on the basis of rainfall rate (table 8) makes no practical difference to the calculated rainfall rates for values of radar reflectivity ≤ 50 dB. The foil data provide drop distributions that are, in most cases, monomodal and feature an expected exponential decay in concentration for drop sizes $\geq 1 \text{ mm}$ in diameter (e.g., fig. 5). The mass integration of the drop size spectrum obtained through the foil analysis usually gives shower-averaged rainfall contents of order 1 gm m^{-3} , a value which appears to be quite reasonable.

The raw (unmodified) drop-spectrum measurements obtained with a raindrop distrometer on the NOAA ship Researcher exhibited strong peculiarities at drop sizes $\lesssim 2 \text{ mm}$. This was most likely caused by insensitivity of the instrument to small drop sizes due to a high level of continuous shipboard noise. As is evident from curve #4 in figure 9, the distrometer-derived drop distributions, on occasion, showed a suspicious-looking multimodal tendency. A comparison of

⁵Note that the relationship $Z = 170R^{1.29}$ was derived only from the distrometer data collected on the NOAA ship Researcher. Results from distrometers on other GATE ships are not discussed in this report.

⁶Geotus (personal communication) has calculated a mean radar reflectivity value of 26 dB with an 8-dB standard deviation for observations taken on board the Gilliss during Phase 3 of GATE. This would indicate, if we assume a normal distribution of reflectivity values, that Z would be expected to exceed 44 dB on only about 5 percent of all occasions.

Table 13. Best-fit Z-R Relationships as a Function of Rainfall Rate (From "Researcher" Distrometer Data)

Stratification	No. data points	Z-R relationship	Correlation coefficient	R at 50 db mm hr ⁻¹	R at 45 db mm hr ⁻¹	R at 40 db mm hr ⁻¹	R at 35 db mm hr ⁻¹

$R > 2.5 \text{ mm hr}^{-1}$	122	$Z = 131 R^{1.37}$	0.967	127	55	24	10
$R > 5.0 \text{ mm hr}^{-1}$	104	$Z = 100 R^{1.45}$	0.963	117	53	24	11
$R > 7.5 \text{ mm hr}^{-1}$	91	$Z = 99 R^{1.45}$	0.960	118	53	24	11
$R > 10.0 \text{ mm hr}^{-1}$	72	$Z = 92 R^{1.47}$	0.950	116	53	24	11
$R > 12.5 \text{ mm hr}^{-1}$	61	$Z = 90 R^{1.48}$	0.947	114	52	24	11

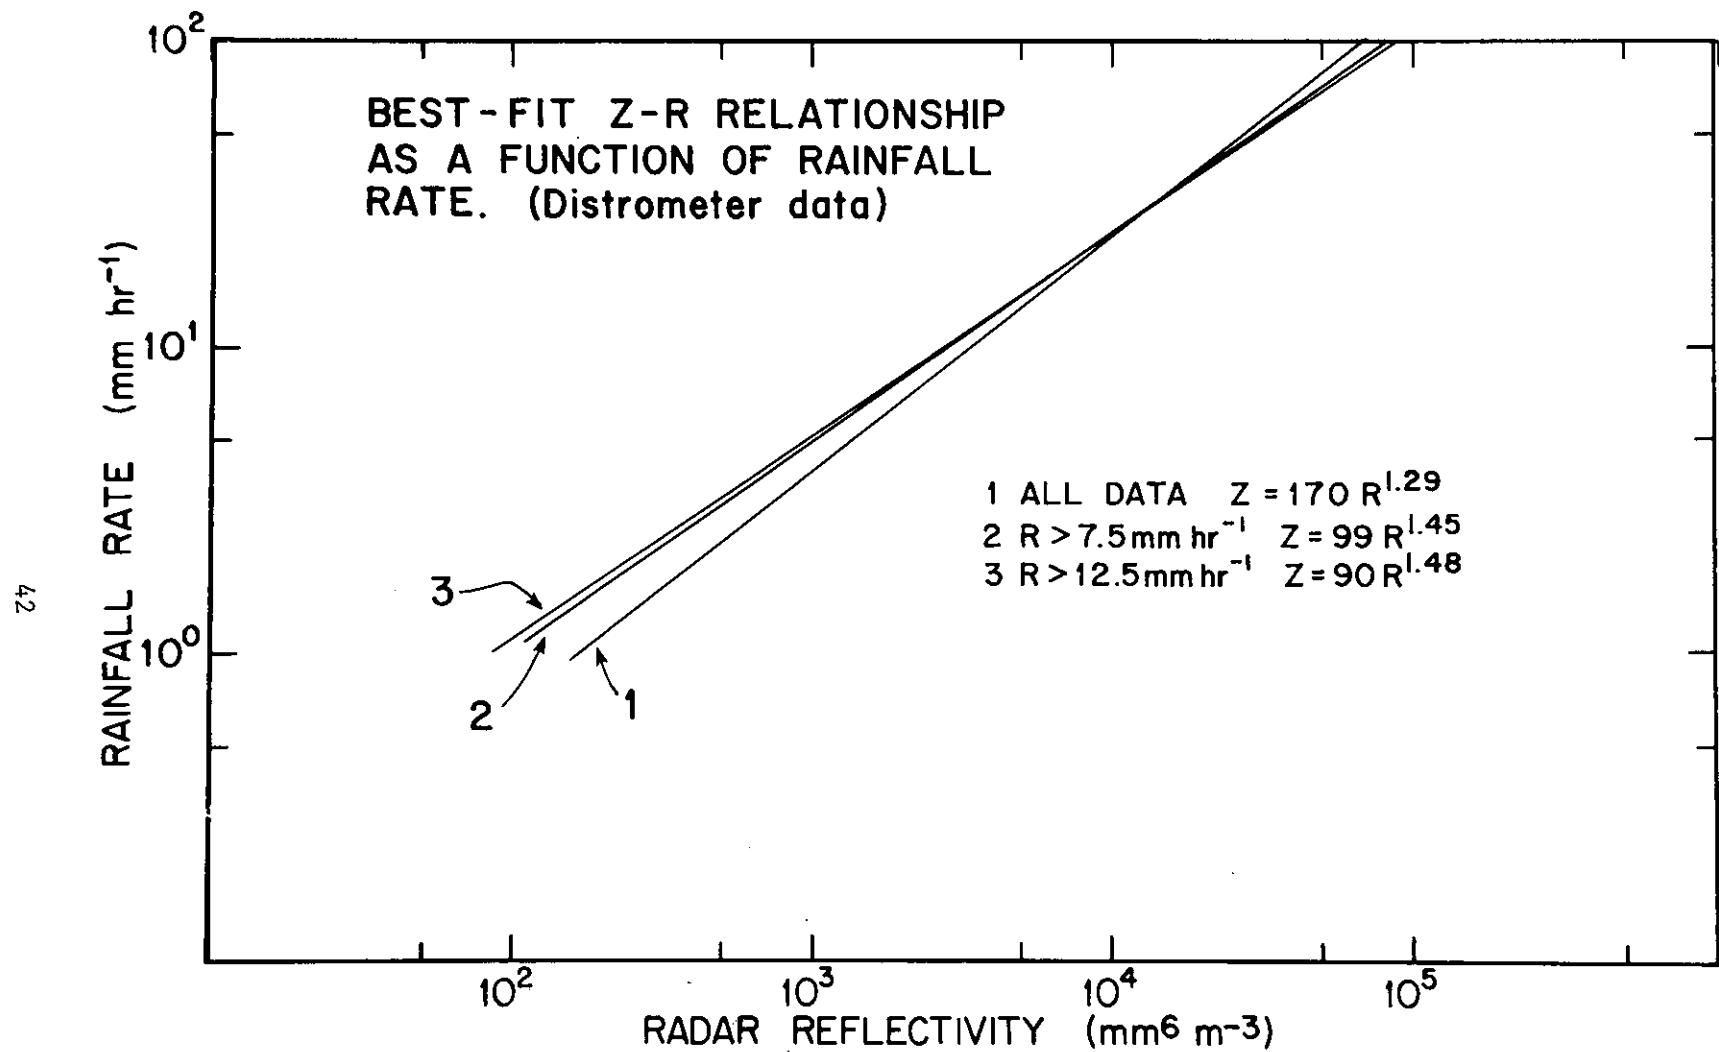

Figure 15. Best-fit Z-R relationship curves as a function of rainfall rate obtained from an analysis of modified "Researcher" distrometer data.

figure 9 with figure 10 demonstrates the type of modification necessary to produce drop spectra, the integration of which provide mass (rainfall depth) measurements more consistent with those obtained by shipboard gages.

The degree to which the best-fit Z-R relationship derived from the raw (unmodified) distrometer data differs from that derived from the corrected (modified) distrometer data can be seen by comparing curves #3 and #4 in figure 16. The Z-R relationship derived from the raw data set has a slightly steeper slope (1.19) than that derived from the modified data set (1.29), but the Z-axis intercept (at $R = 1$) of the latter (170) is much less than that of the former (484). The crossover point for the two curves occurs near a Z value of 70 dB (rainfall rate approximately 4500 mm hr^{-1}) with increasing divergence between the curves at values of $Z < 70 \text{ dB}$. As can be seen from the distrometer section of table 14, this results in a rather large percentage difference in computed rainfall rates between the two curves for all reflectivity values $< 60 \text{ dB}$. Since the range of radar reflectivities of greatest frequency of occurrence within the GATE B-scale array probably lies between 20 and 50 dB, a shift in the best-fit Z-R relationship from the raw to the modified distrometer data set will make a significant difference to the calculated total rain depth as determined from radar.

A comparison of curves #1 and #4 in figure 16 reveals that the best-fit Z-R relationships derived from the aircraft untransformed (raw) foil data and the shipboard-modified distrometer data also diverge from each other. In this case, the crossover point is near 23 dB, but, by 50 dB, the difference in rain rates derived from the two curves exceeds a factor of 2 (see table 14). It is clear, therefore, that the best-fit Z-R relationships for the aircraft (DC-6) foil and shipboard (*Researcher*) distrometer data are not in close agreement. No attempt has been made to derive a best-fit curve from the combined distrometer/foil data set in this study.

A comparison of figure 9 with figure 10 shows that the corrections which had to be applied to the distrometer drop-distribution data at the small end of the spectrum were appreciable. The small end of the drop spectrum was molded by correction factors which, though intuitively consistent with what might reasonably be expected, were applied somewhat arbitrarily. The differences in rainfall rate resulting from such corrections are dramatically apparent in figure 10 where the actual and modified rainfall rates for each of the five curves are shown. The rainfall rates derived from the modified data set were about a factor of 3 greater than those derived from the actual data set for curves #2 through #5. The very light rainfall case, curve #1, was modified by nearly an order of magnitude in rain rate. Although it is clear from the unmodified distrometer data shown in figure 8 that some correction at the small end of the spectrum is necessary, we are not comfortable with the significant changes that such corrections can make to the rainfall rates. The resultant best-fit Z-R relationship to the modified distrometer data has been shaped as much, or more so, by the corrections as by actual recorded data. Therefore, we are forced to question the advisability of relying upon the *Researcher* distrometer as a source of data for the derivation of a valid Z-R relationship for the GATE B-scale array.

Figure 16 and table 14 also give results for the DC-6 foil data transformed through use of a cumulative distribution function. A discussion of the

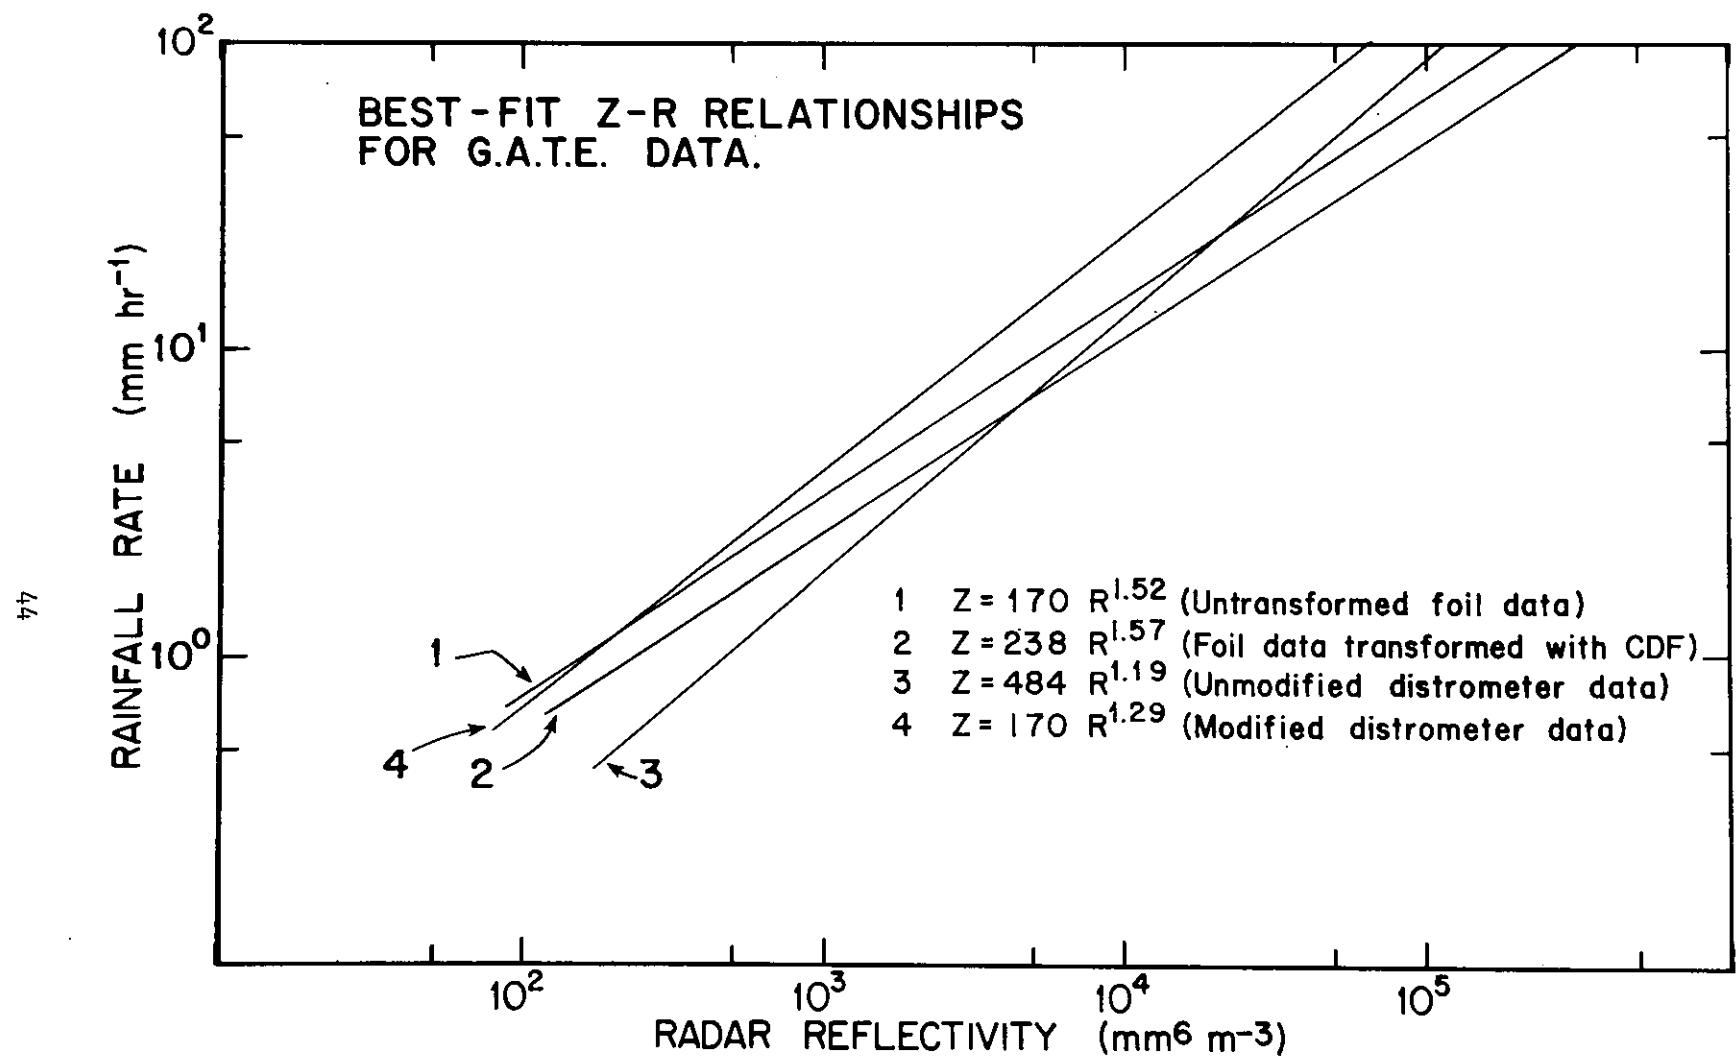

Figure 16. Best-fit Z-R relationship curves for the GATE B-scale array obtained through an analysis of all (1) untransformed DC-6 foil data, (2) CDF-transformed DC-6 foil data, (3) unmodified "Researcher" distrometer data, and (4) modified "Researcher" distrometer data.

Table 14. Rainfall (mm hr^{-1}) as a Function of Radar Reflectivity (db) for Various GATE Z-R Relationships

	(untransformed) $Z = 170 R^{1.52}$	(transformed with CDF) ¹ $Z = 238 R^{1.57}$	(unmodified) $Z = 484 R^{1.19}$	(modified) $Z = 170 R^{1.29}$
60	302	203	611	836
55	142	98	232	342
50	66	47	88	140
45	31	23	34	57
40	15	11	13	24
35	7	5	5	10
30	3	2	2	4
25	2	1	<1	2

¹Transformation of foil data through use of a cumulative distribution function (CDF) is discussed in detail in Appendix C.

rationale and procedure for using such a transformation is presented in Appendix C. Results from the analysis of the untransformed foil data have been presented in the main text because this type of approach is consistent with the many Z-R observations recorded in the literature (e.g., table 1). Although a discussion of the procedure for transforming drop size data through use of a cumulative distribution function has been relegated to an appendix, mainly because of the unconventional nature of that type of analysis, the authors have confidence in the technique and feel that it deserves attention. It can be seen from figure 16 that the slope of the best-fit curve for the untransformed foil data differs little from that for the transformed data. Table 14 shows that the rainfall rates computed from the two best-fit curves differ consistently by about a factor of 1.5 over the whole range of reflectivity values, the rainfall for the transformed data being lower.

For the sake of consistency with other published data, the authors suggest that the best-fit curve to the untransformed foil data

$$Z = 170R^{1.52} \quad (9)$$

best represents the Z-R relationship for the area of the GATE B-scale array. The rain rates as a function of Z derived from (9) give R values of 66, 31, 15, 7, and 3 mm hr⁻¹ for Z values of 50, 45, 40, 35, and 30 dB, respectively. This can be compared to R values of 49, 24, 12, 6, and 3 mm hr⁻¹ for the corresponding Z values (50, 45, 40, 35, and 30 dB) derived from the "classical" Marshall-Palmer (1948) relationship

$$Z = 200R^{1.6} \quad (10)$$

It can be seen that differences in rain rates derived from the two expressions diverge and begin to become appreciable for $Z \leq 40$ dB.

8. SUMMARY AND CONCLUSIONS

Drop spectra data were obtained during GATE with a foil impactor mounted on the wingtip of a NOAA DC-6 aircraft and a distrometer exposed on the flying bridge of the NOAA ship Researcher. Foil data were collected at or near cloud base and were analyzed on a per-rainshaft-penetration basis by an optical scanning device for 12 GATE days, most of which occurred during the second phase. The distrometer data were analyzed in 2-minute intervals for the duration of nine showers that occurred during 8 GATE days. Values of radar reflectivity (Z) and rainfall rate (R) were calculated as a function of the drop size distribution for each analyzed unit. A total of 107 Z-R data points are available from the foil analysis, and 137 Z-R data points are available from the distrometer analysis.

The drop spectra derived from an analysis of the foil data appear reasonable in terms of an exponential decay of the form

$$N(D) = N_0 e^{-\lambda D} \quad (11)$$

for $D \geq 1$ mm. The drop spectra derived from an analysis of the distrometer data, however, are not found, for the most part, to decay exponentially for

$D \leq 2$ mm. It is suspected that a continuous level of shipboard noise resulted in a loss of instrument sensitivity for drops ≤ 2 mm in diameter. A modification of the small end of the drop spectra obtained from the distrometer analysis was attempted with siphon gage data as a means of ground truth comparison. The modification to the spectra resulted in substantial changes in distrometer-derived rainfall rates and calculated radar reflectivities.

The best-fit Z-R relationship to the modified distrometer data set has the form

$$Z = 170R^{1.29}$$

The best-fit Z-R relationship to the foil data (without any transformation) has the form

$$Z = 170R^{1.52}$$

Although the Z-axis intercept (at $R = 1$) is identical in the two expressions, the slopes are sufficiently different to induce rather large differences in R as a function of Z over the important range $Z = 30$ dB to $Z = 50$ dB. We have chosen not to attempt to derive a best-fit expression to a combination of the two sets of data, since each set appears to be mutually exclusive. Because of the arbitrary nature of the rather significant modifications which had to be made to the drop spectra derived from the distrometer, we feel that most weight should be placed on the cloud-base Z-R relationship (9) obtained through the analysis of the foil data.

A method of transforming the foil drop spectra data through a cumulative distribution function is described in Appendix C. This technique allows for the derivation of a best-fit equation to a histogram of drop sizes while maintaining internal consistency between the total drop concentration and the integrated mass of rain water. The main advantage of applying the technique is the alleviation of sampling volume problems which can occur at the large end of the spectrum. This technique is unconventional and inconsistent with the manner in which previously published Z-R relationships have been obtained, but it is felt that such an approach has considerable merit and may be utilized more in the future.

9. ACKNOWLEDGMENTS

Jack Thomas of NHEML's Cumulus Group was responsible for a large portion of the foil impactor data processing, and the authors are most grateful for the care and dedicated effort he displayed in carrying out this very tedious task. Processing of the distrometer data was carried out primarily by Matt Bamberg, now at Florida State University. The authors express gratitude to Dr. William Woodley for his interest and support throughout this study, and to Drs. William Cotton (now at Colorado State University) and Anthony Olson (now at Battelle Northwest) for the mathematical treatment of the cumulative distribution function. The project was funded by the NOAA GATE Project Office.

Appendix A

Drop Size Distributions from the DC-6 Foil Impactor

This appendix presents the complete list of 107 drop size distributions collected near cloud base for the 12 days analyzed for GATE. The heading section for each drop size distribution contains the date, beginning time, sampling duration, and sampling volume for that distribution. It also gives the computed Z and R values from the actual and cumulative distribution function, CDF (see Appendix C) data. Column 1 gives each of the 10 drop size categories. Columns 2 and 3, respectively, give the midpoint diameter for that category and the actual number of drops measured in that category. Columns 4 and 5, respectively, show the normalized distributions for a ΔD spacing of .432 mm and the normalized distributions for a ΔD spacing of 1.0 mm for the actual data set. Columns 6, 7, and 8 present the data derived from the cumulative distribution function. Column 6 gives the number of drops in each drop size category and columns 7 and 8 present the normalized distributions for a ΔD spacing of .432 mm and a ΔD spacing of 1.0 mm, respectively. The minimum and maximum drop diameters for each size category are given at the end of table A-1, page 70.

Appendix B

Drop Size Distributions from the Researcher Distrometer

This appendix presents the complete list of 137 drop size distributions collected at the surface from the NOAA ship Researcher for 9 days analyzed for GATE. The heading section for each drop size distribution contains the date, the beginning time, and the sampling duration, which, for consistency, was kept constant at 120 seconds. It also gives the computed Z and R values for the actual data set and the modified data set. Column 1 gives the 20 drop categories with the midpoint values for each category shown in column 2. The actual number of drops sampled in each category is listed in column 3. Columns 4 and 5, respectively, show the normalized distribution for a ΔD spacing of .25 mm and the normalized distribution for a ΔD spacing of 1.0 mm from the actual data. Columns 6 and 7 present the normalized distributions from the modified data set. Column 6 gives the normalized distribution for a ΔD spacing of .25 mm and column 7 gives the normalized distribution for a ΔD spacing of 1.0 mm.

Table B-1. Drop Distribution Obtained on Board NOAA Ship "Researcher".

Appendix C

Z-R Relationship Derived Through Use of a Cumulative Distribution Function (CDF)

C.1. Rationale: Statistical Considerations

The representativeness of the drop size distribution sampled with a device such as the foil impactor is discussed in a series of papers by Cornford (1967, 1968a, 1968b). Using Poisson statistics, he examined the number density of drops which must be sampled to define accurately the drop size distribution and particle size concentration. Cornford concluded that approximately 400 drops must be counted in each size category (he used .25-mm increments) for the resulting measured drop spectra to be within $\pm 10\%$ of reality on 95% of occasions. If the drop spectra need only be measured to within $\pm 50\%$ on 95% of occasions, only 23 drops must be counted in each size category. There is, of course, some compensation of sampling errors between adjacent size categories when the drop size distribution is integrated to compute, for example, water mass. Thus, it is Cornford's conclusion that drops in concentrations of between 10 and 100 m^{-3} can be defined fairly accurately by an instrument of the foil impactor type. He further concludes, however, that measurements with a foil impactor almost certainly will not be representative of the number of large drops when they occur in concentrations of less than about 2 m^{-3} .

The sampling volume problems inherent in determining representative concentrations of drops at the large end of the spectrum are well recognized. The number density of drops in each size increment varies greatly from shower to shower and is primarily a function of rainfall rate and sampling location within the shower. In the procedure for selecting suitable foil data, only those traverses through rainshaft cores which yielded an integrated sample size of at least several hundred drops were considered for detailed analysis. Although this does not satisfy the strict number density criteria for all size categories established by Cornford, it does serve to eliminate those showers which were not intense enough to produce a representative drop spectrum. It can be seen from the selected and composited drop size distributions shown in Appendix A that no exceptional deviations from an exponential decay are evident at the large end of the spectra.

C.2. Use of the Cumulative Distribution Function

A cumulative distribution function (CDF) has been developed and applied in the hope of eliminating problems associated with small sampling volumes at the large end of the spectrum. As mentioned, because of compensation of sampling errors between adjacent size ranges, the integration of a measured drop size spectrum to determine total water mass is inherently more accurate than the determination of the spectra itself. The CDF transforms the number density of drops within each size category to force conformation to an exponential curve which is physically consistent with respect to both total water content and total drop concentration. This serves to smooth out the sampling irregularities at the large drop sizes and should, in theory, provide a more

realistic indication of the actual drop distribution (assuming that such a distribution is of the preconceived exponential form). To our knowledge, this technique has not been applied outside of NOAA/NHEML. In this appendix, the best-fit Z-R relationship to data points computed from the transformed (CDF) drop distributions is presented and discussed.

C.3. Development of the Cumulative Distribution Function

The foil impactor instrument suffers from a problem common to all air-borne measurement devices that rely upon the direct collection of particulate matter in the atmosphere--it cannot sample a volume of cloud large enough to insure a statistically acceptable concentration of drops in all size categories. The sampling volume problem increases in severity as the drop diameter becomes larger. In the larger raindrop size categories (corresponding to drops $> 3 \text{ mm}$ in diameter), it is not unusual to sample with the foil impactor only a few drops during an aircraft traverse through a cloud volume of 1 to 10 m^3 . The use of a cumulative distribution function alleviates problems caused by reasonable statistical fluctuations in the sampled data set if it can be assumed that there exists one theoretical function that can characterize the real drop distribution within all clouds or rainshafts of interest.

A distribution of the type suggested by Marshall and Palmer (1948) has been generally used to characterize raindrop spectra in a variety of cloud conditions. This function has the form

$$N(D) = N_0 e^{-\lambda D} \quad (\text{A.1})$$

with the slope, λ , related to rainfall rate through the expression

$$\lambda = 4.1R^{-0.21} \text{ mm}^{-1} \quad (\text{R in mm hr}^{-1}) \quad (\text{A.2})$$

and N_0 given the value: $8000 \text{ m}^{-3} \text{ mm}^{-1}$. Note that this distribution function is strictly valid only for drop spectra which display an exponential decrease in concentration with increasing size, and it should not be applied if bimodal (or otherwise non-exponential) real distributions are suspected.

Figure C.1 shows a raindrop distribution generated through (A.1) with the data given in table C.1.⁷ Let us assume that the real raindrop size spectrum in a given rainshaft is represented by the curve (line) in figure C.1. Now suppose that 1 m^3 of the rainshaft is sampled with a foil impactor and the data appear as shown in table C.1 and the histogram in figure C.2. In comparing figure C.1 with figure C.2, one can see that the drop concentrations in the two smallest size categories, each of which has a relatively large data sample, remain unchanged, while in the fourth size category and greater, the sampled data set departs significantly from the assumed real exponential drop distribution. Curve A in figure C.2, a best fit to the sampled data, gives values of 11556 and 3.08 for N_0 and λ , respectively. The differences at the

⁷The data set of table C.1 has been developed as an idealistic example of how the CDF operates. It is not part of the GATE data set.

large end of the spectrum between the collected data and the real distribution can be interpreted as due to sampling volume problems, and thus the best-fit curve A in figure C.2 does not provide an accurate representation of the assumed real drop size distribution (curve C in figure C.2 or the curve in figure C.1).

The use of a cumulative distribution function partly eliminates sampling volume problems. The integration of (A.1) to find the total number of drops (N_T) over all size categories yields

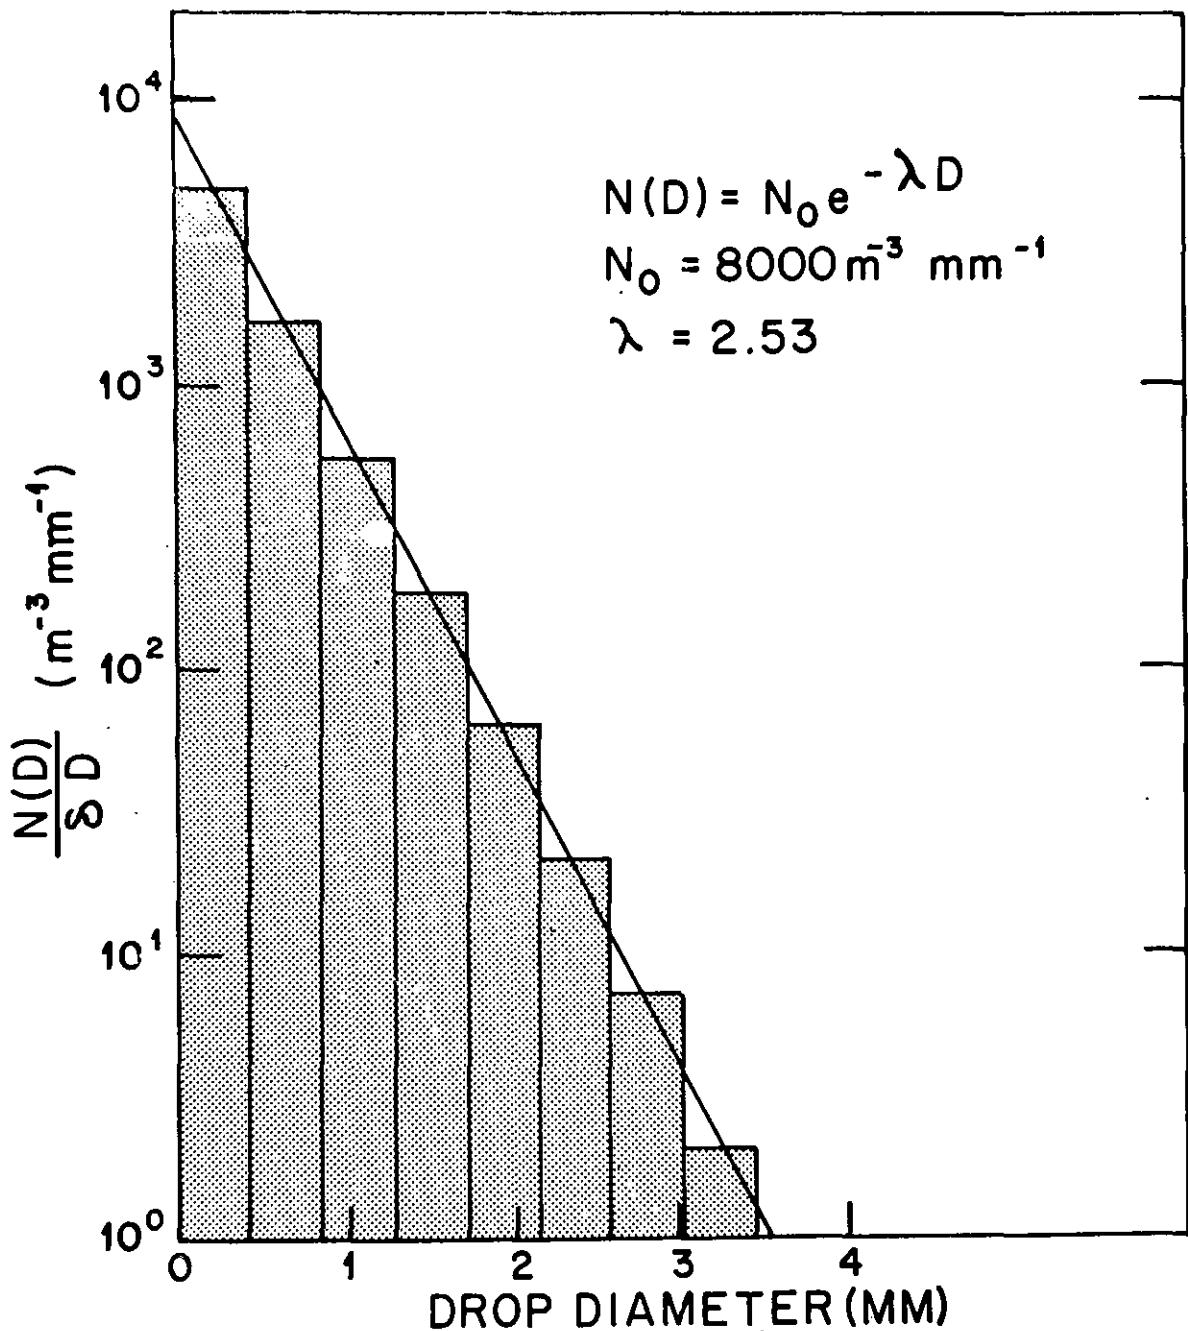

Figure C.1. An idealistic assumed Marshall-Palmer drop size distribution.

Table C-1. Drop Distribution Data

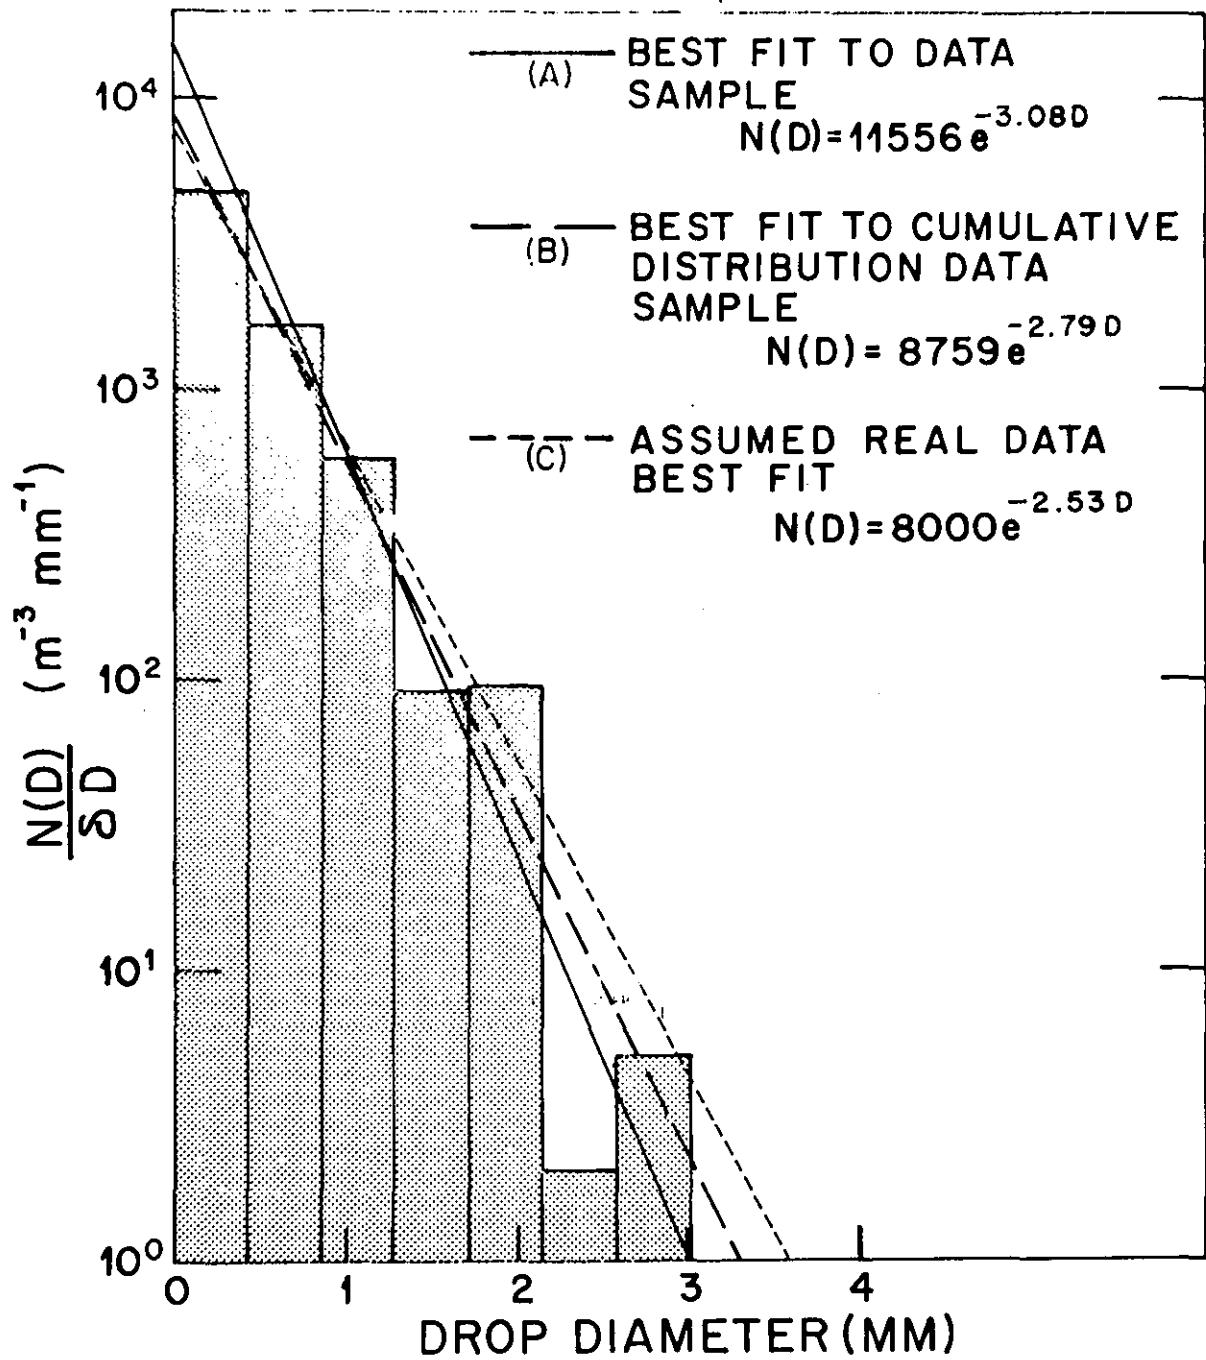

Size category	Minimum diameter (mm)	Mean diameter (mm)	Maximum diameter (mm)	Assumed real drop concentration ¹ no m ⁻³	Assumed real drop concentration ¹ no m ⁻³	Sample drop distribution ² no/m ³ /δD	Sample drop distribution ² no m ⁻³	Expected drop concentration ³ no m ⁻³ mm ⁻¹

102

¹Calculated from exponential distribution: $N(D) = N_0 e^{-\lambda D}$ with N_0 assumed $8000 \text{ m}^{-3} \text{ mm}^{-1}$ and λ of 2.53 derived from assumed rainfall rate of 10 mm hr^{-1} .

²Hypothetical 1 m^3 data sample which might be obtained from real distribution by use of foil impactor.

³Derived from cumulative distribution function.

C.2. Best-fit curves drawn to (A) histogram of sampled drop sizes shown, (B) real drop sizes shown transformed through use of a cumulative distribution function, and (C) assumed real distribution shown in figure C.1.

$$N_T = \frac{N_0}{\lambda} \left[1 - e^{-\lambda D} \right] \Big|_0^\infty \quad (A.3)$$

which gives

$$N_T = \sum N_i = \frac{N_0}{\lambda} \quad . \quad (A.4)$$

The total water content of the experimental distribution can be found by integrating the expression

$$M = \int_0^\infty \frac{\pi \rho D^3}{6} N_0 e^{-\lambda D} dD \quad (A.5)$$

which, when solved, gives

$$M = \frac{\pi \rho N_0}{6} \frac{\Gamma(4)}{\lambda^4} \quad . \quad (A.6)$$

The mass (liquid water content) can also be computed independently from

$$M = \frac{\rho \pi}{6} \sum N_i D_i^3 \quad (A.7)$$

where N_i and D_i are the concentration of drops and mean mass drop diameter,⁸ respectively, of interval i . Substituting (A.4) into (A.6) and solving for λ gives

$$\lambda = \left[\frac{\pi \rho \Gamma(4)}{6} \right]^{1/3} N_T^{1/3} M^{-1/3} \quad . \quad (A.8)$$

The cumulative distribution function therefore provides a Y-axis intercept (N_0) and a slope (λ) to a best-fit exponential curve. N_0 and λ are physically consistent with respect to total water content (M) and total drop concentration (N_T). Note that the calculated values of M and N are derived from the observed data set and thus are subject to errors caused by sampling volume problems discussed earlier. However, the effect of sampling volume errors on total mass and total concentration is not nearly as great as that on the drop concentration within each interval. The use of the cumulative distribution function, defined as

$$C(D) = \frac{N_0}{\lambda} (1 - e^{-\lambda D}) \quad , \quad (A.9)$$

⁸The "mean mass diameter" is not necessarily located at the midpoint diameter of each interval, although the latter is generally used in practice to compute the total mass.

serves to smooth out the sampling irregularities at the larger drop sizes and should, in theory, provide a better indication of the real drop distribution.

It can be seen from curve B in figure C.2 that the best-fit relationship derived through use of the cumulative distribution function approximates the assumed actual distribution (curve C in figure C.2) much more closely than does the best fit to the sampled data (curve A in figure C.2). The calculated values of $N_0 = 8759$ and $\lambda = 2.79$ from the cumulative distribution function are very close to the assumed real values of $N = 8000$ and $\lambda = 2.53$.

C.4. Application to GATE Drop Distribution Data Obtained from Foil

Figure C.3 shows the five selected drop size distributions for August 10, 1974, as transformed through use of the CDF. The best-fit expression of the form

$$N(D) = N_0 e^{-\lambda D}$$

is given for each case. This can be compared with the data given in figure 5.

Figure C.4 is a plot of all the Z-R data points derived through a CDF transformation of the raw spectra (see Appendix A for a complete listing) and gives the best-fit curve to the data. The best-fit curve to the untransformed data (fig. 7) is also given for comparison. The best-fit curve for the CDF-transformed foil data is found to have the form

$$Z = 238R^{1.57} \quad (\text{A.10})$$

Table C.2 shows the rainfall rate (mm hr^{-1}) as a function of $Z(\text{dB})$ for eight daily GATE Z-R relationships calculated from CDF-transformed drop distribution data collected near cloud base by the foil impactor on the DC-6 aircraft. These results can be compared with those of the untransformed foil data shown in table 7. The daily variability in rain rates computed from radar reflectivities of 35 to 50 dB does not appear to be of significance. Some divergence in the calculated daily rain rates for very heavy rainfalls ($Z > 50 \text{ dB}$) is observed. Figure C.5 shows a plot for all of the daily Z-R relationships calculated from the CDF-transformed drop distribution data.

Figure C.6 shows the best-fit Z-R relationship as a function of three rain rates ($R > 0$, $R > 7.5 \text{ mm hr}^{-1}$, and $R > 12.5 \text{ mm hr}^{-1}$) for the CDF-transformed data. This can be compared to figure 8. These curves from the CDF data appear to be somewhat more sensitive to rain rate stratification than those shown for the untransformed data. The complete Z-R data stratified as a function of rain rate is given in table C.3, which is analogous to table 8.

The use of the CDF transformation has not been a conventional technique for previously published analyses of Z-R relationships. For consistency with other observations (table 1), therefore, we have not emphasized the CDF results in the main section of the report. However, use of the CDF to eliminate sampling volume problems at the large end of the droplet spectra has obvious advantages and may provide results which are more representative of the actual rainfall-reflectivity relationship.

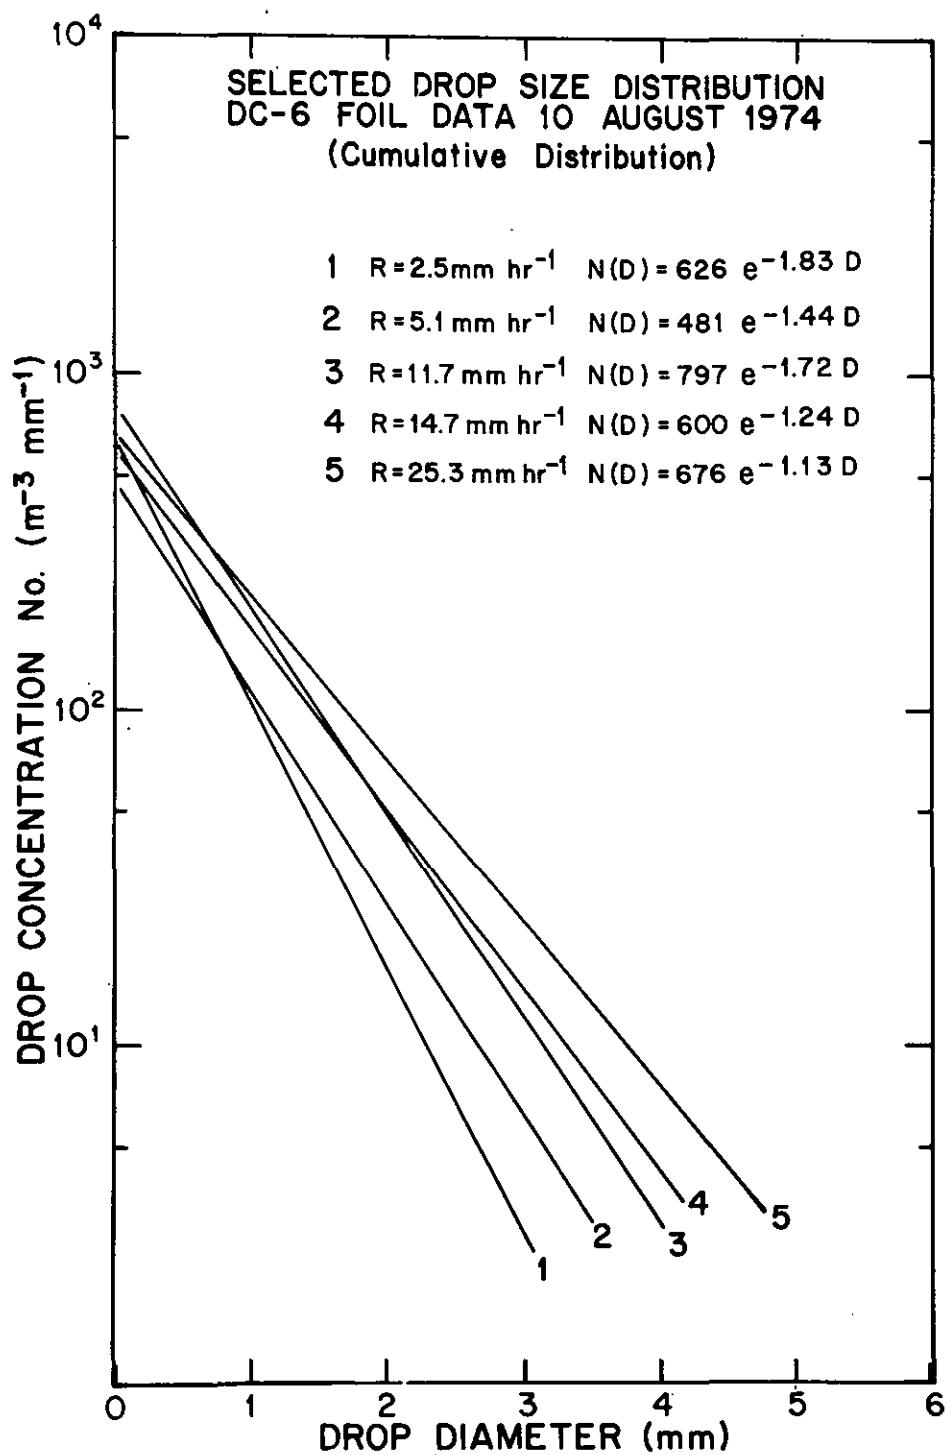

Figure C.3. As in figure 5, except drop size distributions transformed through use of the CDF.

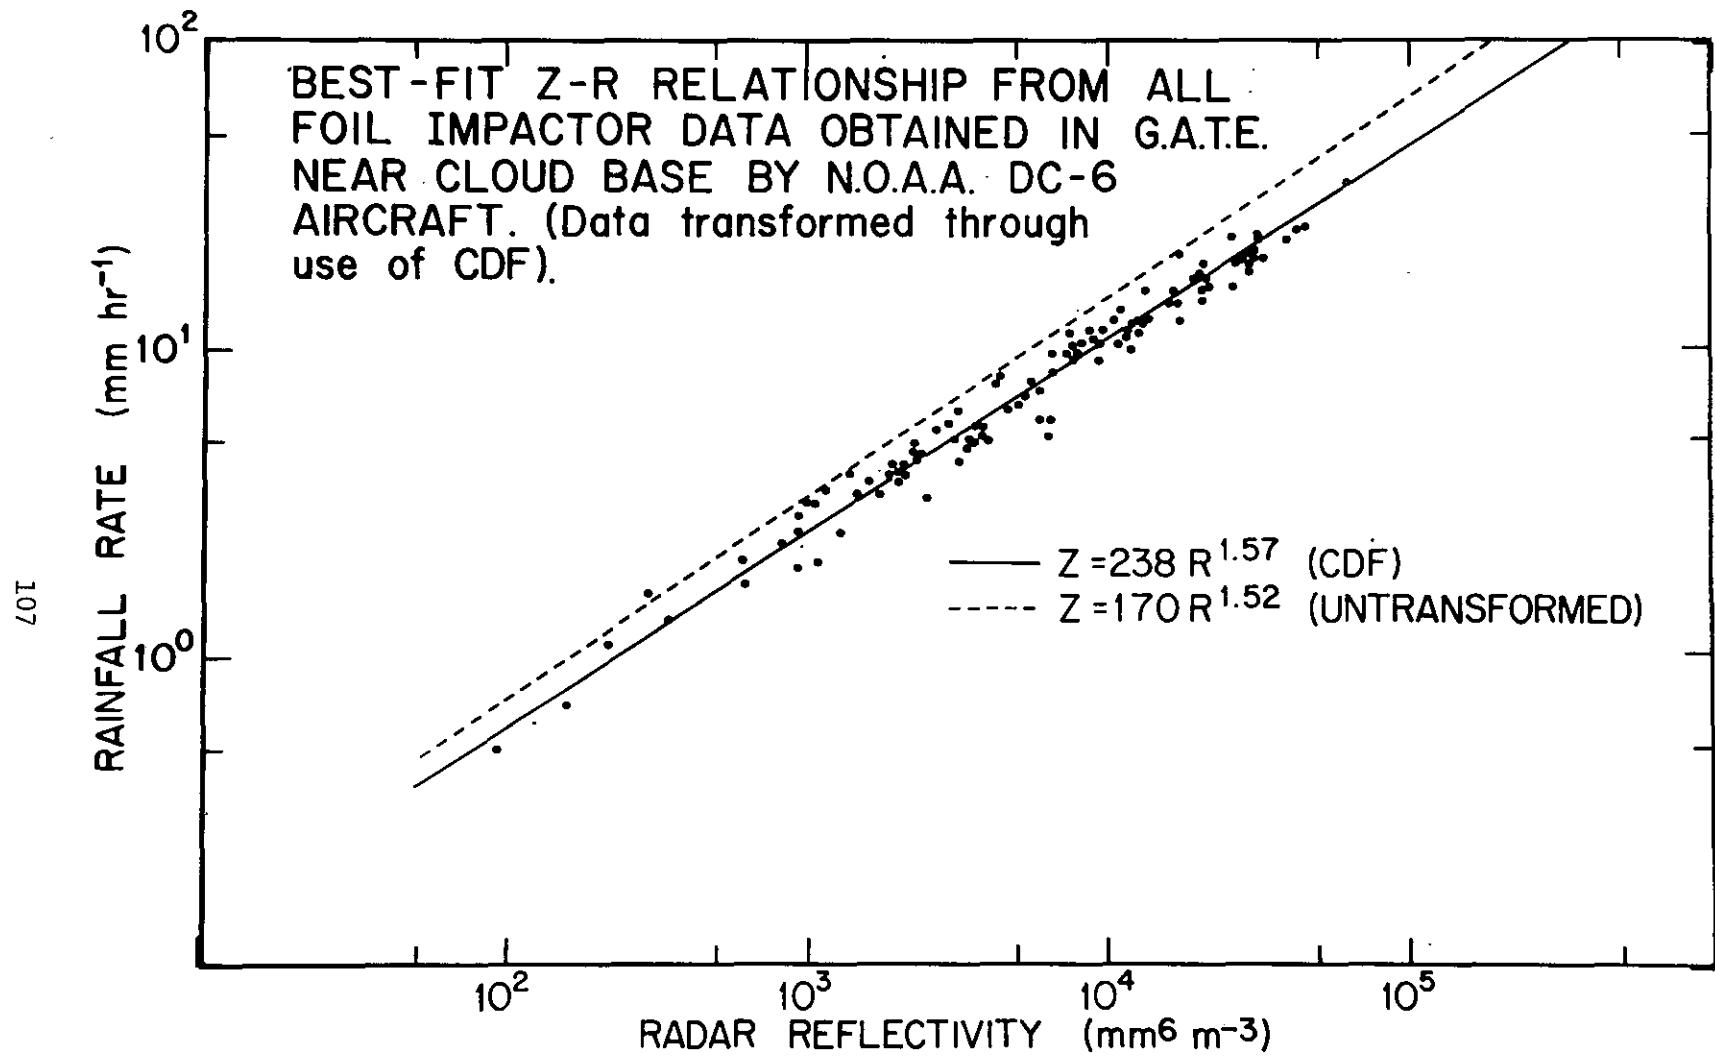

Figure C.4. Best-fit Z-R relationship drawn to all data points obtained through an analysis of DC-6 foil data transformed through use of the CDF. Best-fit curve to the untransformed data (fig. 7) included for comparison.

Table C-2. Rainfall Rates (mm hr^{-1}) as a Function of Z (db) for Eight Daily Z-R Relationships Obtained at Cloud Base During GATE (CDF data)

Z(db)	$230R^{1.58}$	$251R^{1.57}$	$269R^{1.47}$	$235R^{1.49}$	$343R^{1.46}$	$493R^{1.36}$	$259R^{1.56}$	$204R^{1.68}$

**Program Listings and Sample Output for
Foil and Distrometer Data Analysis**

Foil Program - Listing and Sample Output

A fortran listing is provided for the NOAA/NHEML foil data processing program. This program takes as input a histogram of number densities of drops obtained per ten .43-mm-diameter intervals during the aircraft traverse of a rainshaft and produces as output a series of tables and graphs. These tables and graphs show drop concentration in units L^{-4} , computed water contents, mean and median diameters and volume diameters, computed values of reflectivity (Z) and rain rate (R), best-fit curves to the distribution data, and derived values of λ and N_0 in the exponential best-fit equation. This set of information is derived for both the actual data and that transformed through use of the cumulative distribution function (expected data). A linear best fit to the Z and R data points is computed for both the actual and CDF data. (See distrometer output in next section for example.)

The program consists of a main section (in which all data is read, all bookkeeping functions are handled, and all output is written) and nine subroutines (CALC, RAIN, V WATER, V DROP, MEDIAN, LEASTQ, REGR, PLOTT, and ZRFIT) in which computations are performed. The listing contains a number of comment cards designed to assist the reader in interpreting the purpose of each section of the program.

```

***** PROGRAM FOIL EML *****
THIS PROGRAM CALCULATES OBSERVED AND EXPECTED WATER DROP SIZE
DISTRIBUTIONS FROM FOIL IMPACTOR DATA.

Distrometer Program - Listing and Sample Output

A fortran listing is provided for the NOAA/NHEML distrometer data processing program which takes as input the drop concentration per expanded bin interval of .25 mm (19 bins shown in table 4) and derives the rain rate R by computing the mass of rain (grams) impacting upon 1 cm² of the distrometer sensor head per bin per sampling duration (listed as 120 sec). Radar reflectivity Z is computed directly from the concentration of drops accumulated in each bin size. The best-fit Z-R equation is formulated within subroutine ZR. The output data includes the number density and concentration (cm⁻³) per each .25-mm bin, the calculated Z and R values, the rainfall depth in mm accumulated, and, as shown on the final page, the coefficient "a" and exponent "b" resulting from a linear regression best-fit of the Z-R data set to the expression: $Z = aR^b$.
